TECHNIQUES FOR ESTIMATING 7-DAY, 10-YEAR LOW-FLOW CHARACTERISTICS FOR UNGAGED SITES ON STREAMS IN MISSISSIPPI

by Pamela A. Telis

ABSTRACT

Mississippi State water laws require that the 7-day, 10-year low-flow characteristic (7Q10) of streams be used as a criterion for issuing waste-discharge permits to dischargers to streams and for limiting withdrawals of water from streams. This report presents techniques for estimating the 7Q10 for ungaged sites on streams in Mississippi based on the availability of base-flow discharge measurements at the site, location of nearby gaged sites on the same stream, and drainage area of the ungaged site. These techniques may be used to estimate the 7Q10 at sites on natural, unregulated or partially regulated, and non-tidal streams. Low-flow characteristics for streams in the Mississippi River alluvial plain were not estimated because the annual low-flow data exhibit decreasing trends with time. Also presented are estimates of the 7Q10 for 493 gaged sites on Mississippi streams.

Techniques for estimating the 7Q10 have been developed for ungaged sites with base-flow discharge measurements, for ungaged sites on gaged streams, and for ungaged sites on ungaged streams. For an ungaged site with one or more base-flow discharge measurements, base-flow discharge data at the ungaged site are related to concurrent discharge data at a nearby gaged site. For ungaged sites on gaged streams, several methods of transferring the 7Q10 from a gaged site to an ungaged site were developed; the resulting 7Q10 values are based on drainage area prorations for the sites. For ungaged sites on ungaged streams, the 7Q10 is estimated from a map developed for this study that shows the unit 7Q10 (7Q10 per square mile of drainage area) for ungaged basins in the State. The mapped values were estimated from the unit 7Q10 determined for nearby gaged basins, adjusted on the basis of the geology and topography of the ungaged basins.

INTRODUCTION

Knowledge of the magnitude and frequency of low-flow discharges is important for water-supply planning; waste-load allocation; storage-facility design; and maintenance of quantity and quality of water for irrigation, recreation, and wildlife conservation. In Mississippi, city planners and water managers must address issues involving the availability of streamflow for dilution and transport of waste effluent and the reliability and quality of surface water for supply. Although Mississippi is a water-rich State, receiving approximately 56 in. of rainfall statewide per year (Wax, 1982), the demand for surface water, particularly during the driest months (usually September through November) when minimum streamflow occurs, can result in flows of insufficient quantity and unacceptable quality for surface-water users.

A low-flow characteristic is defined as the annual minimum average discharge for a selected consecutive-day period for a given recurrence interval in years. For example, a 7-day, 10-year low-flow characteristic (7Q10) of 12 ft³/s for a site indicates that the annual minimum average discharge for 7 consecutive days is equal to or less than 12 ft³/s, on average, once in 10 years. The inverse of the recurrence interval is the probability of occurrence; therefore, for this example, a 10 percent chance exists that the annual minimum average discharge for 7 consecutive days for any given year will be equal to or less than 12 ft³/s. Average consecutive-day discharges can be computed for various recurrence intervals. Other examples of low-flow characteristics that are commonly used in water-resources planning include the 7-day, 2-year (7Q2), the 7-day, 20-year (7Q20), and the 3-day, 20-year (3Q20) low-flow characteristics.

In Mississippi, the 7Q10 is used as a criterion by State and local water managers to permit a specified quantity of waste effluent to be discharged to streams and to set permit limits for surface-water withdrawals from streams. For example, State water laws promulgated in 1985 require that surface-water users can be "permit[ted] the use of water of any stream only in excess of the established minimum flow..." and define "established minimum flow" to be "the average streamflow rate over seven (7) consecutive days that may be expected to be reached as an annual minimum no more frequently than one (1) year in ten (10)" (State of Mississippi, 1985). Therefore, accurate estimates of the 7Q10 for Mississippi streams are essential for the management of the State's water resources in compliance with State law.

Background

In a previous study, Tharpe (1975) determined low-flow characteristics (7Q2 and 7Q10) for 433 streamflow gaging stations in Mississippi. To estimate the 7Q10 for ungaged sites in Mississippi, Tharpe developed a map showing

the generalized geographic variation of the unit 7Q10 (7Q10 per square mile of drainage area) for the State.

In 1984, the U.S. Geological Survey, in cooperation with the Pat Harrison Waterway District; the Pearl River Basin Development District; the Tombigbee River Valley Water Management District; and two agencies of the Mississippi Department of Environmental Quality [formerly the Department of Natural Resources], the Office of Land and Water Resources and the Office of Pollution Control, began a study to determine low-flow characteristics for an expanded statewide network of streamflow gaging stations and to improve techniques for estimating the 7Q10 for ungaged sites. Telis (1991) presented low-flow characteristics (7Q2, 7Q10, and 7Q20) for 105 continuous-record gaging stations and low-flow characteristics (7Q2 and 7Q10) for 430 partial-record gaging stations on natural and unregulated streams in Mississippi and adjacent States. In that study, low-flow characteristics for 406 of the 433 gaging stations included in the study by Tharpe (1975) were updated based on as much as 20 additional years of streamflow data and on improved statistical analysis procedures. This report (also a product of the 1984 cooperative agreement) presents techniques for estimating the 7Q10 for ungaged sites in Mississippi and is based on the low-flow characteristics determined by Telis (1991).

Purpose and Scope

This report presents techniques for estimating the 7Q10 for ungaged sites on streams in Mississippi based on the availability of base-flow discharge measurements at the site, location of nearby gaged sites on the same stream, and drainage area of the ungaged site. Techniques are presented for (1) ungaged sites with base-flow discharge measurements, (2) ungaged sites on gaged streams, and (3) ungaged sites on ungaged streams.

The techniques described in this report are used to estimate the 7Q10 for sites on natural, unregulated or partially-regulated, non-tidal streams. The annual low-flow data for streams in the Mississippi River alluvial plain exhibit a decreasing trend with time; therefore low-flow characteristics were not estimated in this region.

For Mississippi streams, low-flow data from streamflow sites having less than approximately 45 percent of the drainage area regulated generally do not violate assumptions for frequency analyses and are analyzed similarly to data from natural streamflow sites. Low-flow frequency analyses of streamflow data are not valid for regulated streams (those having more than approximately 45 percent of the drainage area regulated) because of the irregular and nonprobabilistic pattern of flow. Legal minimum discharges required to be released at operated impoundments may provide estimates of minimum expected streamflow downstream of flow-regulating structures.

BASE-FLOW HYDROLOGY, PHYSIOGRAPHY, AND GEOLOGY

The base flow, or low flow, of natural streams is derived from the discharge of ground water to stream channels. The rate of ground water discharge to a stream is determined by several factors, such as the hydraulic gradient toward the stream, the hydraulic properties of the geologic formations or aquifers underlying the basin, the degree of incision of the channel into the water-table aquifer, and the channel length and slope. These and other factors relate in a complex manner to control base-flow yields from a basin. Generally, for Mississippi streams, areas with similar base-flow yields per square mile correspond with outcrop areas of similar geologic units. However, a single value of base flow per square mile may not accurately represent the hydrologic conditions of basins for streams that cross several outcrop areas. Similarly, there may be very different base-flow yields from adjacent basins in areas having springs. A spring in the headwaters of one tributary may cause that stream to have a higher base-flow yield than a stream in an adjacent basin that does not have a spring.

The State of Mississippi lies within the east Gulf Coastal Plain physiographic province and can be subdivided into 10 distinct physiographic regions (Fenneman, 1938) as shown in figure 1. These physiographic regions reflect areas of different topography, geology, soils, and vegetation within the State. A range of unit-7Q₂ values for gaged basins having drainage areas less than about 400 mi² is presented for each physiographic region in the following paragraphs. In this section, unit-7Q₂ values are indicators of base-flow yields and are computed from the 7Q₂ for gaged sites presented by Telis (1991).

The Fall Line Hills region is characterized by rugged topography and streams that are deeply incised. These hills are underlain by moderately resistant clay, gravel, and sand of the Tuscaloosa and Eutaw Formations, and the Coffee Sand, all of Cretaceous age. Base-flow yields to streams range from 0.2 to 0.4 (ft³/s)/mi² in the eastern part of the region where streams have cut into the highly permeable Tuscaloosa Formation. Base-flow yields to streams are lower [0.02 to 0.1 (ft³/s)/mi²] for the less permeable formations in the western part of the region.

The Black Prairies region is characterized by low rolling hills and wide floodplains underlain by chalk and marl of the Selma Group of Cretaceous age. Most streams draining this region cease flowing during the dry season.

The Pontotoc Hills region is a narrow, rugged upland that has been deeply dissected by stream action into a series of elongated hills and valleys. The hills are underlain by deposits of the Ripley and Owl Creek Formations of Cretaceous age, and the Clayton Formation of Paleocene age. Base-flow yields to streams range from 0.02 to 0.2 (ft³/s)/mi² in this region.

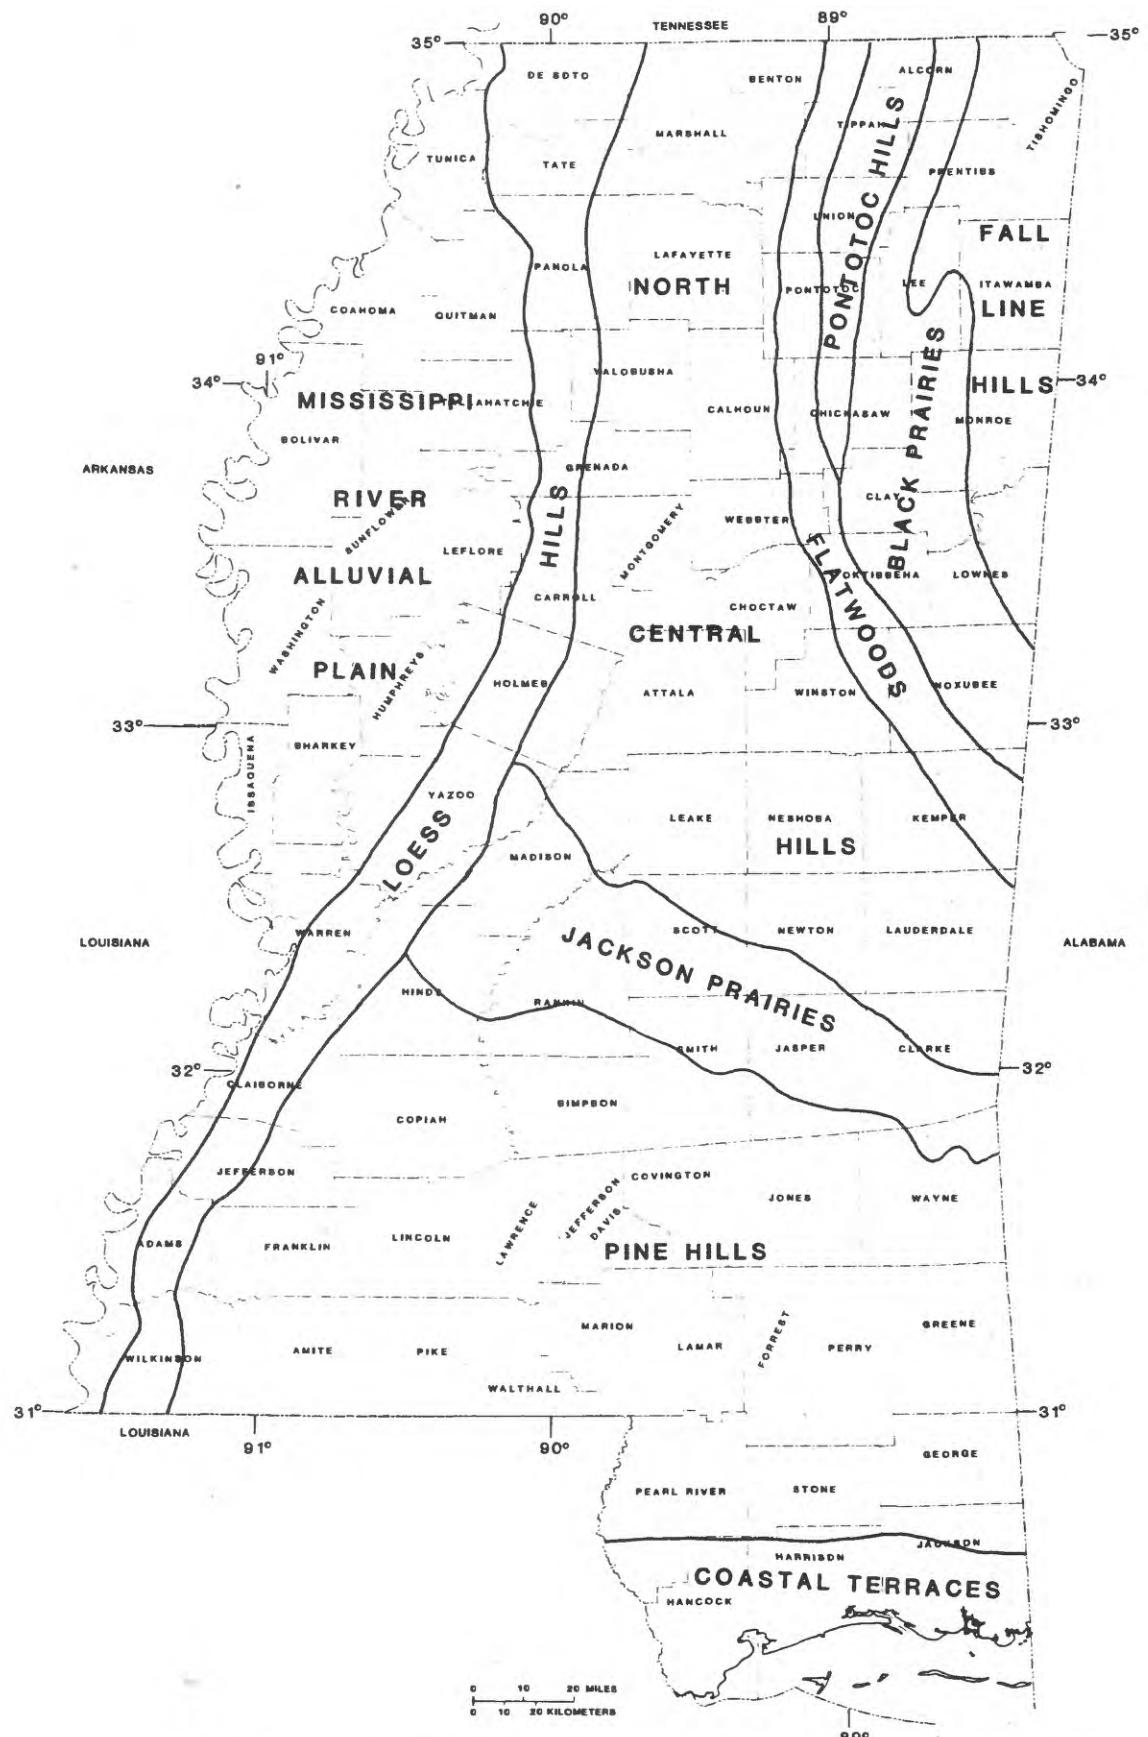

Figure 1.--Physiographic regions of Mississippi (modified from Fenneman, 1938).

The Flatwoods region is a narrow, flat to slightly rolling area underlain mainly by the Porters Creek Clay of Paleocene age. The stream valleys in this area are broad with low, flat divides. The impermeable Porters Creek Clay causes rapid runoff during storms and produces base-flow yield to streams of less than $0.1 \text{ (ft}^3/\text{s)}/\text{mi}^2$. Several large streams in this region receive little base flow and cease to flow during the dry months of most years.

The North Central Hills region is characterized by rolling hills that are deeply dissected by streams. Most of the region is underlain by unconsolidated sand and clay of the Wilcox and Claiborne Groups of Tertiary age. In the southeastern part of the region, outcrops of resistant siliceous sandstone and clay of the Tallahatta Formation of Tertiary age predominate. Base-flow yields ranging from 0.4 to $2.0 \text{ (ft}^3/\text{s)}/\text{mi}^2$ result from somewhat sandy surficial material in the northern part of the region. Yields less than $0.1 \text{ (ft}^3/\text{s)}/\text{mi}^2$ occur in the southern part of the region where the clay of the Tallahatta Formation is at the surface.

The Jackson Prairies region is a gently rolling area where large streams have broad valleys. The northern and western parts are underlain by clay of the Jackson Group, and southern parts are underlain by sandy marl and limestone of the Vicksburg Group, both of Tertiary age. The thick and impermeable clay of the Jackson Group produces streams with little or no base flow during the dry months. Streams draining the Vicksburg Group have slightly higher base flow but yields are less than $0.1 \text{ (ft}^3/\text{s)}/\text{mi}^2$.

The Pine Hills region is characterized by low, rounded dissected hills. Large streams have wide, flat valleys with swamps common in lowland areas adjacent to the streams. The region is underlain by alternating beds of clay, sandy clay, and sand of undifferentiated Miocene deposits and by gravel and sand of the Citronelle Formation of Pliocene age. Base-flow yields ranging from 1.0 to $2.0 \text{ (ft}^3/\text{s)}/\text{mi}^2$ are common in streams draining deposits of the Citronelle Formation, which are capable of storing large volumes of precipitation during wet periods and slowly releasing water to streams during dry periods. Additionally, springs at the base of the Citronelle Formation help maintain base flow in streams in this region. Base-flow yields less than $1.0 \text{ (ft}^3/\text{s)}/\text{mi}^2$ occur in areas where surficial geology is dominated by the less permeable clay of the Miocene deposits.

The Coastal Terraces region is a low, flat or slightly undulating plain along the Mississippi Gulf Coast underlain by coastal deposits of clay, loam, and sand and by gravel and sand of the Citronelle Formation. There are numerous swamps and marshes adjacent to the coast that extend inland along the streams that drain the coastal area. The water table is at or near the surface in this region and sluggish streams flow in tortuous channels.

Streams flowing from outcrops of the Citronelle Formation have substantial base flows. Base-flow yields for the region range from 0.1 to 0.4 (ft^3/s)/mi².

The Loess Hills region has steep slopes with narrow ridges and valleys. It is underlain by a thick deposit of Pleistocene loess (windblown silt) which decreases in thickness to the east. Low infiltration rates for the loess result in rapid runoff of storm water and in base-flow yields of less than 0.1 (ft^3/s)/mi² to streams.

The Mississippi River alluvial plain region is a flat expanse characterized by extremely sinuous stream courses, swamps, and poorly defined drainage divides. The region is underlain by highly permeable sandy Quaternary alluvium capped by a clay layer that averages about 20 ft in thickness. Low-flow characteristics for streams in this region were not estimated because the annual low-flow data exhibit a significantly decreasing trend with time (Telis, 1991). Increased ground-water withdrawals have caused regional ground-water declines averaging 4 ft during 1980-89 (G.D.S. Goldsmith, U.S. Geological Survey, oral commun., 1989) and have resulted in decreased ground-water discharge to streams. Prior to regional ground-water-level declines, larger streams that cut through the clay cap and drain the alluvium had sustained base flows, whereas small streams that had channels within the clay layer ceased flowing during the dry months.

TECHNIQUES FOR ESTIMATING 7-DAY, 10-YEAR LOW-FLOW CHARACTERISTICS FOR UNGAGED SITES ON MISSISSIPPI STREAMS

Multiple regression analyses of basin and climatic parameters commonly are used to provide equations for estimating discharges for selected recurrence intervals for ungaged sites. However, the use of multiple regression equations to estimate low-flow characteristics at ungaged sites often results in equations with unacceptably high standard errors of estimate. If a parameter that characterizes the geology of the basin is included in the regression analysis, standard errors of estimate often are greatly reduced. The use of a streamflow recession index (Bingham, 1986) or a flow-duration ratio (Arihood and Glatfelter, 1986), which might be used to characterize the geology of stream basins, was expected to improve the results of the regression analysis for streams in Mississippi. However, attempts to characterize basin geology using streamflow recession indices and flow-duration ratios and to divide the State into regions with similar recession indices or flow-duration ratios were unsuccessful because of the lack of gaging stations within small basins that drain areas of homogeneous geology. In addition, the multiple regression analyses resulted in only two statistically significant explanatory variables, drainage area and either the streamflow recession index or the flow-duration ratio. Because the low-flow characteristic (7Q10) was directly proportional to the drainage area, a map

delineating areas of similar streamflow recession indices or flow-duration ratios for the State was virtually equivalent to a map delineating areas with similar unit-7Q10 values. Therefore, use of a map showing geographic variation of unit 7Q10 was judged to be a more direct method for estimating low-flow characteristics at ungaged sites.

Alternative techniques were developed for estimating the 7Q10 for ungaged sites on Mississippi streams based on the availability of base-flow discharge data at the ungaged site, the proximity of gaged sites to the ungaged site, and the drainage area of the sites. Techniques are presented for: (1) ungaged sites with base-flow discharge measurements, (2) ungaged sites on gaged streams, and (3) ungaged sites on ungaged streams. Techniques based on discharge measurements at the ungaged site generally are the most accurate because the estimate of the 7Q10 is based directly on streamflow data at the site. In contrast, techniques for estimating the 7Q10 for ungaged sites on ungaged streams are the least accurate of those developed in this study because specific sites generally are not accurately represented by generalized or regional estimates.

Estimates of the 7Q10 for gaged sites on natural, unregulated, and non-tidal streams (Telis, 1991) are included in this report, and are used in the techniques for estimating the 7Q10 for ungaged sites with base-flow measurements and for ungaged sites on gaged streams. In addition, the geographic variation of unit 7Q10 for ungaged areas (plate 1) was developed, in part, from the unit-7Q10 values for the gaged basins in the State.

In this report, gaged sites, or gages, refer to continuous-record and partial-record gaging stations in Mississippi with low-flow characteristics reported by Telis (1991). Continuous-record streamflow gaging stations are those for which discharge data are collected at regular intervals (such as hourly). For this study, low-flow characteristics were computed based on the log-Pearson Type III distribution for continuous-record gaging stations that had periods of record of 10 years or more.

Low-flow partial-record stations are defined in this study to be either streamflow sites where several base-flow discharge measurements were made during several separate streamflow recessions or continuous-record gaging stations with less than 10 years of record. Low-flow characteristics for these partial-record gaging stations were computed by first correlating low-flow discharge measurements made at those stations with concurrent daily discharges at long-term continuous-record gaging stations. The relation is defined by the line of correlation determined from a technique known as MOVE.1, Maintenance of Variance Extension, Type I (Hirsch, 1982) or by a

graphically determined best-fit line described by Riggs (1969, p. 10). The low-flow characteristics at the partial-record stations were then determined through the correlation using the corresponding characteristics at the long-term stations.

For partial-record stations with several observations of zero flow, low-flow characteristics could not be estimated using correlation plots. If the flow at the partial-record station is zero when the concurrent flow at a nearby continuous-record gaging station is greater than the 7Q10 for that station, then the 7Q10 for the partial-record station was estimated to be zero.

Locations of the 493 gaged sites are shown on plate 1. The 7Q10 from the report by Telis (1991) for these gaged sites and estimates of error associated with the low-flow characteristics are presented in table 1, which also includes the station name, station location, type of station (continuous-record station or partial-record station), and drainage area at the site. For the estimation of errors of the 7Q10 for gaged sites, the State is divided into seven areas (fig. 2) for which regional estimates of error were determined. The area of each gaged site is indicated in table 1. To aid the user in locating gaged sites, the gages are listed alphabetically by station name in table 2.

Several methods were used to determine the estimates of error of the 7Q10 for gaged sites based on the method of computation of the low-flow characteristic. For 7Q10 values based on the log-Pearson Type III distribution, the time-sampling error computed by an equation developed by Kite (1988) provides an estimate of the standard error at the gage (Telis, 1991). For those gaged sites having annual 7-day low-flow values equal to zero and the 7Q10 computed to be zero, the time-sampling error could not be determined using the equation by Kite. The error of the 7Q10 at these gaged sites was not determined but is estimated to be approximately 1 percent.

For partial-record stations where the 7Q10 is based on a correlation using the MOVE.1 line, the standard errors of the low-flow characteristics are computed using the standard errors of prediction of the MOVE.1 line and the time-sampling errors for the correlated continuous-record gages (Telis, 1991). If the correlation for the partial-record station was based on a graphically determined best-fit line, an estimate of the error is based on the location of the site.

For each area delineated in figure 2, the errors of the 7Q10 for the partial-record gaging stations where the 7Q10 is based on the MOVE.1 line are plotted with the number of measurements at the site in figure 3. The regional estimate of error for each area was determined by using the trimmed mean (the lowest 5 percent and the highest 5 percent of the error values were excluded) and rounding it to one significant figure. The estimates of error of 7Q10 for the partial-record gaging stations where the 7Q10 is determined

EXPLANATION

- PARTIAL-RECORD STATION

Figure 3.--Regional errors of the 7Q10 for partial-record stations located in areas delineated in figure 2.

graphically are based on these regional values. Errors at these stations are estimated to be some value greater than the regional error associated with the area. For example, the estimate of error of the graphically determined 7Q10 for a partial-record site located in the Pascagoula basin (in Area G) is greater than 30 percent.

For partial-record sites where no flow has been observed and when the flow at nearby gages is substantially greater than the 7Q10 flow, the estimate of the 7Q10 is almost certainly zero. The estimate of error of the 7Q10 for these partial-record sites was not determined but is estimated to be approximately 5 percent.

The errors of the 7Q10 for the gaged sites provide an estimate of the error of the estimated 7Q10 for the ungaged site. The error of the estimate of the 7Q10 for the ungaged site includes the time-sampling error at the gaged site used in the estimation technique in addition to the error associated with the technique. Errors associated with each technique were not determined in this study, but the error of the estimate of the 7Q10 at the ungaged site is some value greater than the time-sampling error for the gaged site. For the technique using the unit 7Q10 shown on Plate 1, the errors at nearby gaged sites provide a minimum error associated with the estimate of the 7Q10 for the ungaged site.

Ungaged Sites with Base-Flow Measurements

For an ungaged site where base-flow discharge measurements are available, the 7Q10 can be estimated by relating base-flow discharge data at the site with concurrent discharge data at a nearby gaged site (from table 1). For each base-flow measurement made at the ungaged site, a concurrent discharge value at the selected gage must be obtained. If the gage is a continuous-record gaging station currently operated by the U.S. Geological Survey or other agency, a daily mean discharge can be obtained from that agency. Otherwise, concurrent discharge measurements are needed at the gaged and ungaged sites.

Adherence to the following criteria for selecting the nearby gage and the hydrologic conditions during which base-flow discharge measurements are made improves the accuracy of the estimated 7Q10. The basin of the gaged site should be hydrologically similar to the basin of the ungaged site with respect to the size of drainage area, surficial geology, and topography. In addition, discharge measurements should be made after several days with no rain to ensure that streamflow does not contain surface runoff. Large basins may require a week or more without rain for surface runoff to cease and for the stream to return to base-flow conditions.

A graphical method may be used for ungaged sites with more than one base-flow measurement (Riggs, 1968). This method uses concurrent base-flow discharges at the gaged and ungaged sites and provides a graphical determination of the estimated 7Q10 for the ungaged site. Riggs (1968, p. 10) indicates that "eight to ten measurements made on different recessions and in more than one year should provide adequate data to define a relation" between two nearby streamflow sites. To determine the relation between flows at the two sites, the logarithms of the measured discharges at the ungaged site are plotted against the logarithms of the concurrent discharges at the gaged site (fig. 4). A graphically determined best-fit line through the data and the 7Q10 for the gaged site are used as the basis for estimating low-flow characteristics for the ungaged site.

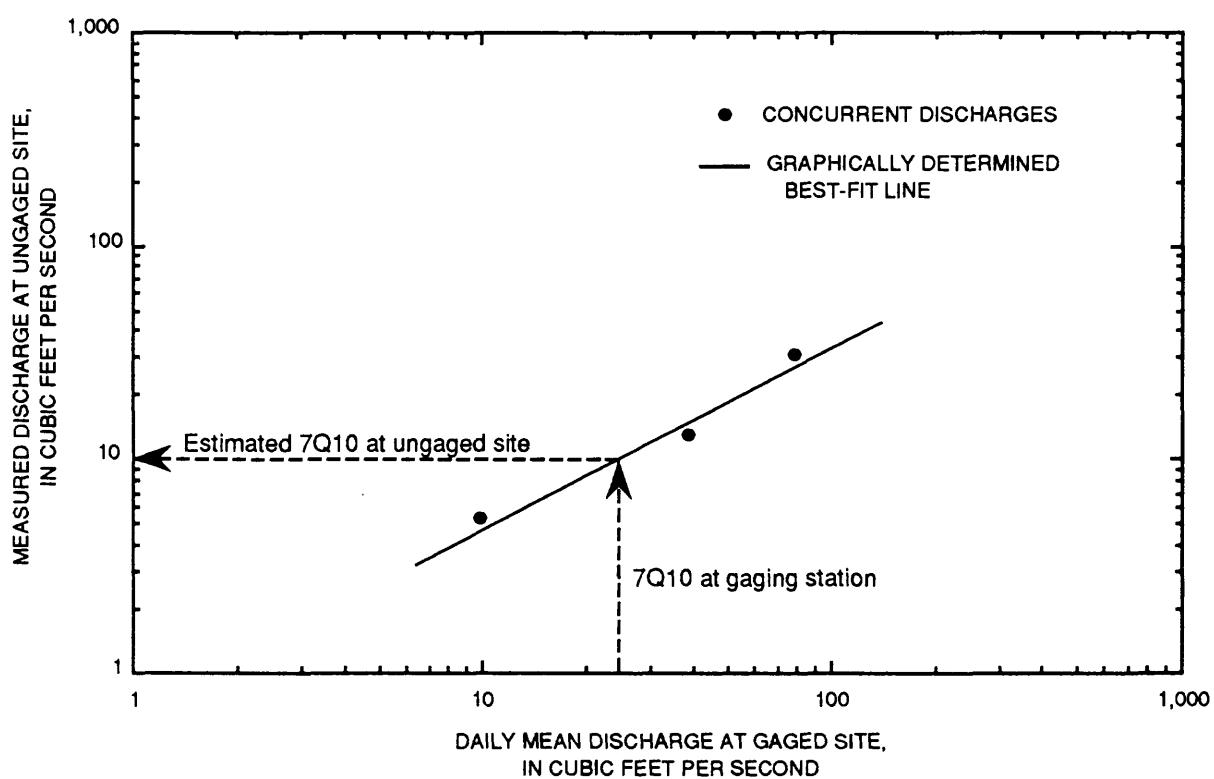

Figure 4.--Relation between base-flow discharge at an ungaged site and concurrent discharge at a nearby gaging station.

For ungaged sites with only one base-flow discharge measurement, the discharge-ratio method (Thomson and Carter, 1963) generally provides a good estimate of the 7Q10 for Mississippi streams. This method relates discharge data at the ungaged site to discharge data at a gaged site. The ratio of concurrent base flows at both sites is assumed to be equal to the ratio of the selected low-flow characteristics for the sites and can be used to estimate the 7Q10 for the ungaged site, as follows:

$$\frac{Q_0}{Q_1} = \frac{7Q_{10_0}}{7Q_{10_1}} \quad (1)$$

where:

- Q_0 is the discharge, in ft^3/s , at the ungaged site during base-flow conditions;
- Q_1 is the concurrent discharge, in ft^3/s , at a nearby gage;
- $7Q_{10_0}$ is the $7Q_{10}$, in ft^3/s , for the ungaged site; and
- $7Q_{10_1}$ is the $7Q_{10}$, in ft^3/s , for the gage from table 1.

The discharge-ratio method is based on the assumption that the base flow in a natural stream varies proportionally with the base flow in a nearby natural stream which drains a basin with similar topography and geology. Base flow in a stream varies proportionally if it decreased by 10 percent in the same period that the base flow decreased 10 percent in a nearby stream draining a hydrologically similar basin. Use of the discharge-ratio method to estimate low-flow characteristics for ungaged sites is based on the assumption that specific base-flow conditions, such as during $7Q_{10}$ conditions, occur concurrently in the basins.

Ungaged Sites on a Gaged Stream

If an ungaged site on a gaged stream has no base-flow discharge data available, its low-flow characteristics can be estimated from low-flow characteristics for a gaged site on the stream. Estimates of the $7Q_{10}$ for ungaged sites can be transferred from a gaged site on the basis of drainage area using the equation:

$$7Q_{10_0} = \left(\frac{A_0}{A_1} \right)^{1.0} 7Q_{10_1} \quad (2)$$

where

- $7Q_{10_0}$ is the $7Q_{10}$, in ft^3/s , for the ungaged site;
- A_0 is the drainage area, in mi^2 , at the ungaged site;
- A_1 is the drainage area, in mi^2 , at the gaged site; and
- $7Q_{10_1}$ is the $7Q_{10}$, in ft^3/s , for the gaged site.

This transfer equation was developed from pairs of gaged sites that are on the same stream and have $7Q_{10}$ values greater than zero. Data for 243 station pairs are listed in the Appendix and include the station numbers, the drainage area ratio (drainage area at the upstream site divided by drainage area at the downstream site), and the discharge ratio ($7Q_{10}$ for the upstream site divided by $7Q_{10}$ for the downstream site) for each pair. The pairs for

which the discharge ratio either is less than 0.17, exceeds two times the corresponding drainage area ratio, or is less than half the corresponding drainage area ratio were not used to calibrate the discharge-drainage area relation. These pairs indicate that factors other than drainage area influence base-flow yields in the basin. For several of these pairs, the upstream site is near the point in the stream where the streamflow changes from flowing to dry during 7Q10 conditions. For other pairs, the upper parts of the basins are underlain with clays which result in low base-flow yields. Therefore, for both cases, the 7Q10 for the upstream site is unusually small compared to the 7Q10 for the downstream site where the factors affecting the low flows at the upstream site have less influence than at the downstream site.

A logarithmic regression of the discharge ratios and the drainage area ratios for 159 station pairs defines the discharge-drainage area relation in equation 2. For these stations pairs, the range of drainage area ratios is 0.19 to 0.99, and the range of discharge ratios is 0.17 to 0.99. The logarithms of the discharge ratio are plotted against the logarithms of the drainage area ratio in figure 5. The data points for station pairs not used in the analysis are indicated in this figure. The slope of the logarithmic regression line from figure 6 is the exponent of the drainage area ratio in equation 2 when the logarithmic equation is converted to a power-law equation. The exponent of the drainage area ratio computed for each station pair used in the regression is listed in the Appendix.

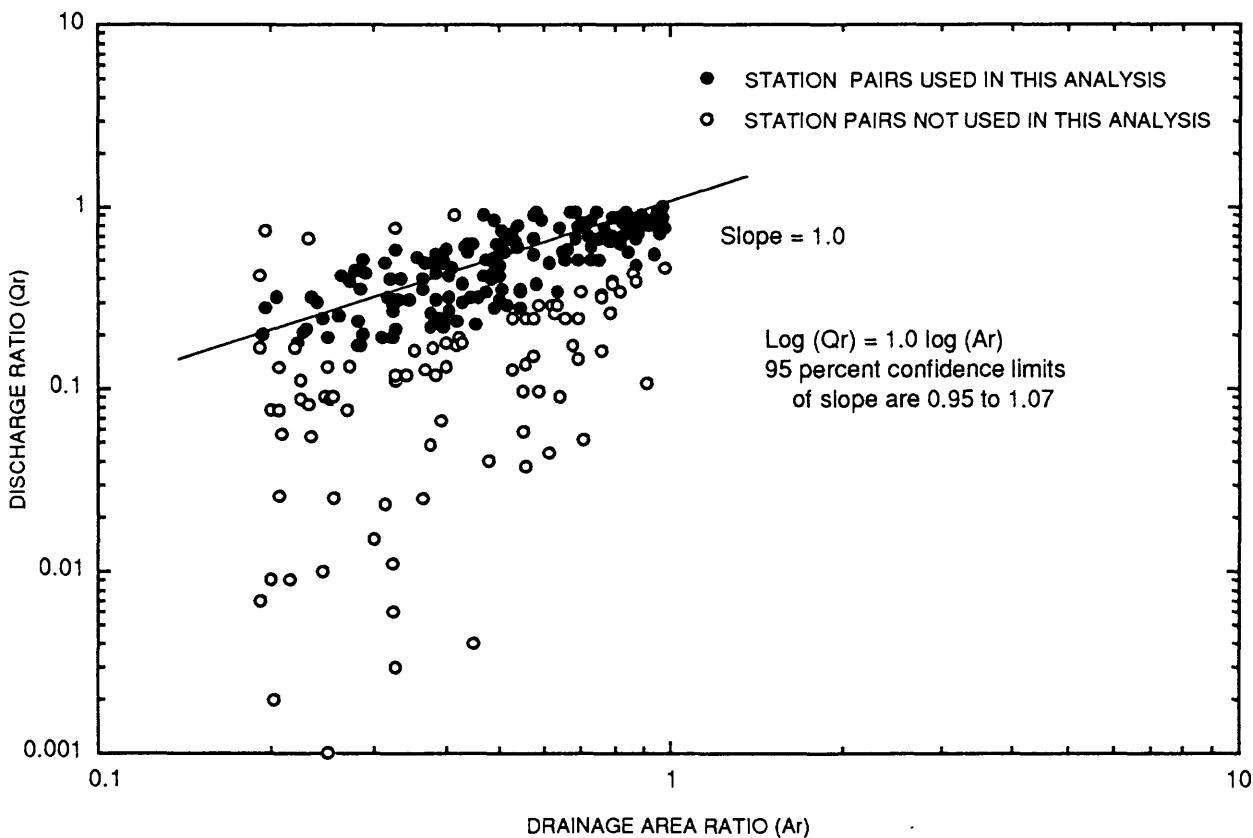

Figure 5.--Relation between discharge ratio and drainage-area ratio for station pairs on the same stream.

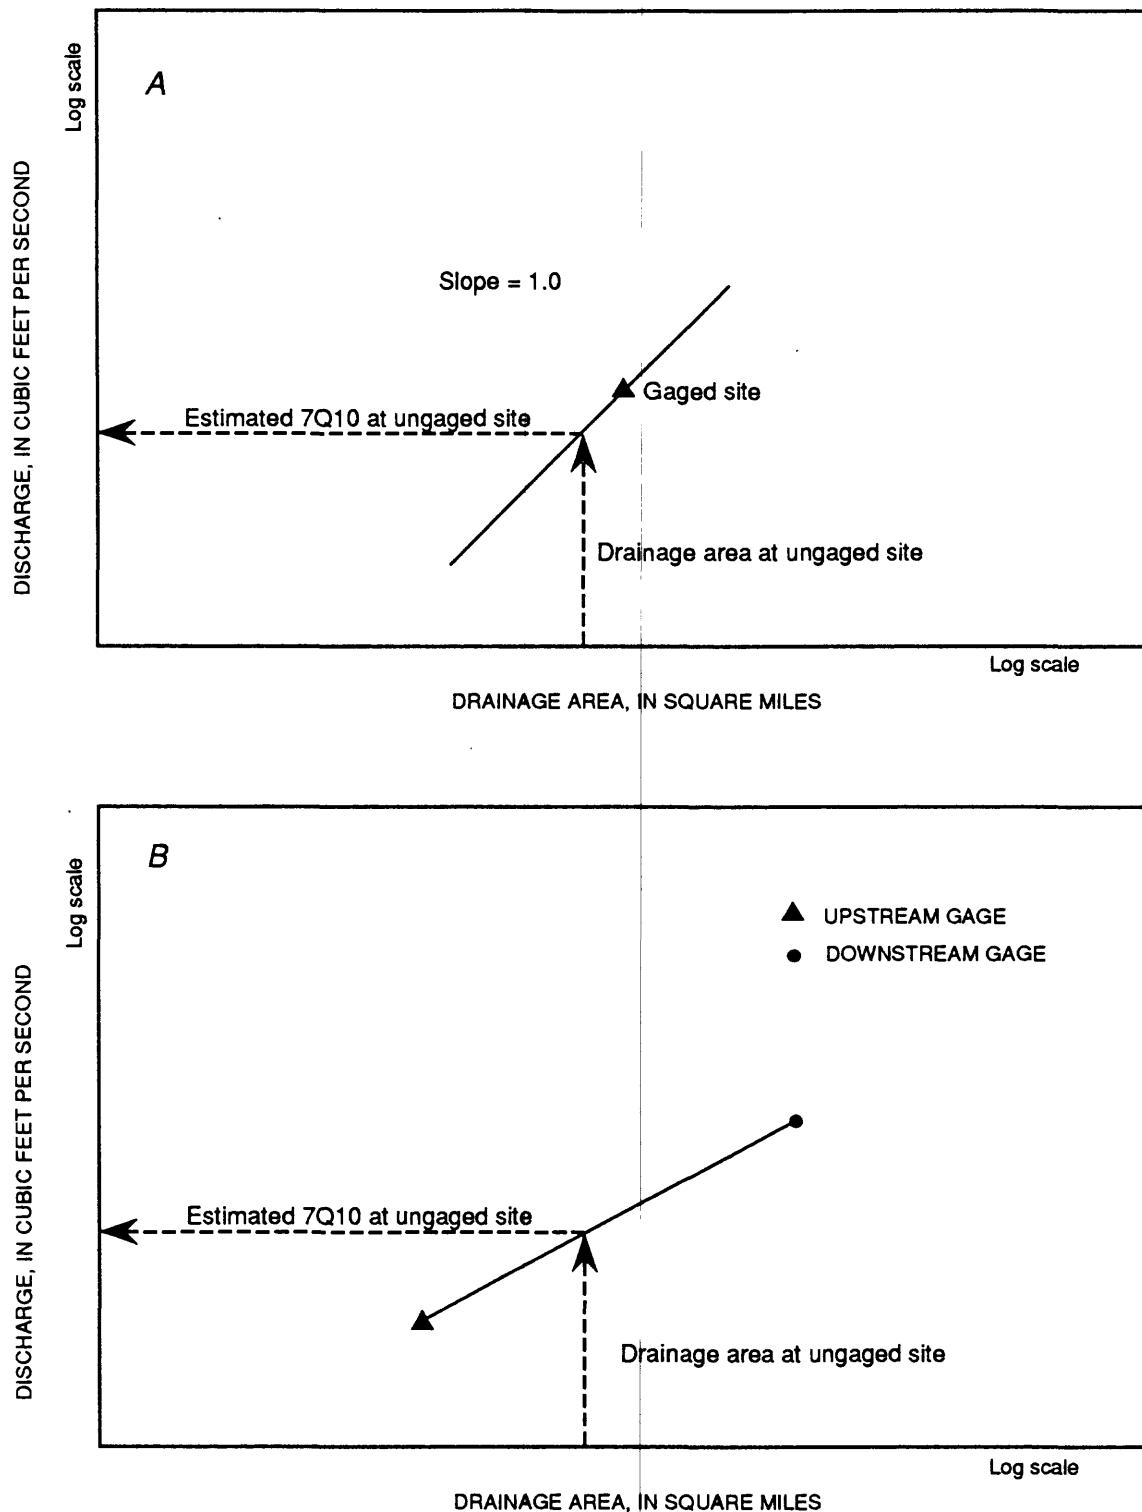

Figure 6.--Estimation of the 7Q10 for an ungaged site on a gaged stream: A. Drainage area proration for an ungaged site having a gaged site either upstream or downstream; B. Logarithmic interpolation for an ungaged site having gaged sites both upstream and downstream.

For an ungaged site having gaged sites both upstream and downstream, the 7Q10 can be estimated by logarithmically interpolating on the basis of drainage area between the estimates of the 7Q10 values for the gages (fig. 6) using the equation:

$$7Q10_0 = \left(\frac{A_0}{A_1} \right)^P 7Q10_1 \quad (3)$$

$$P = \frac{\log \left(\frac{7Q10_2}{7Q10_1} \right)}{\log \left(\frac{A_2}{A_1} \right)} \quad (4)$$

where

- | | |
|----------|---|
| $7Q10_0$ | is the 7Q10, in ft^3/s , for the ungaged site; |
| A_0 | is the drainage area, in mi^2 , at the ungaged site; |
| A_1 | is the drainage area, in mi^2 , at the upstream gaged site; |
| $7Q10_1$ | is the 7Q10, in ft^3/s , for the upstream gaged site; |
| $7Q10_2$ | is the 7Q10, in ft^3/s , for the downstream gaged site; and |
| A_2 | is the drainage area, in mi^2 , at the downstream gaged site. |

Care should be taken when extrapolating the 7Q10 to an ungaged site on the basis of drainage area; however, it is reasonable to assume that estimates of the 7Q10 for ungaged sites are valid when transferred upstream and downstream a limited distance from the gaged site. If the underlying geology of the ungaged basin is different from that of the gaged basin or if the drainage area of the two sites is significantly different, this method of transferring low-flow characteristics might not be appropriate. In this case, base-flow discharge measurements might be used to identify differences in the basins and for estimating the 7Q10 for the ungaged site.

Ungaged Sites on an Ungaged Stream

The 7Q10 is estimated for ungaged sites on ungaged streams from unit-7Q10 values for the ungaged basins shown on plate 1. These unit-7Q10 values are based on the 7Q10 for nearby gaged sites and on the geology and topography of the ungaged basin. An estimate of the 7Q10 for the ungaged site is computed by multiplying the unit-7Q10 value for the basin by the drainage area for the site.

The map showing unit-7Q10 values for ungaged basins (plate 1) was developed for this study by first delineating the drainage basins for gages which have drainage areas less than 300 mi^2 from table 1. A 1:500,000 State map was used for delineation; therefore, approximate drainage boundaries

are shown. The area outside these gaged basins is considered to be the ungaged basins or areas in the State.

The estimates of unit-7Q10 were determined for these ungaged basins or areas. Unit 7Q10 was computed for nearby gaged basins for comparison. State and county geologic and topographic maps provided information about the potential base-flow yields in the area. Although this technique assumes the base-flow discharge per square mile of drainage area is uniform for basins, the streamflow yields actually may vary due to differences in surficial geology, topography, the degree of channel incision, and other factors. Base-flow discharge data can provide information necessary for identifying these differences.

Main-stem streams in these ungaged areas may have gaged sites with drainage areas greater than 300 mi² (table 1). For ungaged sites on these main-stem gaged streams, the 7Q10 is estimated by transferring the 7Q10 for the gage to the ungaged site using equation 2 or equation 3 as described previously.

ASSUMPTIONS AND LIMITATIONS

The techniques described in this report are based on several important assumptions about the accuracy of the estimates of the 7Q10 for gages, the occurrence of the 7Q10 in a basin, the current hydrologic conditions in the basin, and the future climatic conditions.

Techniques for transferring the 7Q10 from gaged sites to ungaged sites and for estimating the 7Q10 from unit-7Q10 values on plate 1 are valid only for streams that flow during 7Q10 low-flow conditions. For gaged sites having the 7Q10 equal to zero in table 1, it is assumed that all stream reaches upstream cease flowing during 7Q10 conditions.

In addition, the 7Q10 is assumed to occur simultaneously at all sites in the basin. However, a reach of stream approaches 7Q10 conditions as a result of some combination of regional and local factors; therefore, this assumption probably is not valid for all sites in a basin.

For frequency analyses, the assumption is that hydrologic and climatic conditions in the past are characteristic of the current and future conditions; that is, these conditions are not changing with time. However, ongoing urbanization, which reduces infiltration rates, and large-scale ground-water pumping, which reduces ground-water levels in surficial aquifers, are examples of changing factors that result in decreased ground-water discharge to streams. Similarly, channelization can increase ground-water discharge to streams. Natural, long-term changes in climate would similarly violate the assumptions required for frequency analyses. Knowledge of past conditions and potential changes in the basin or of climate changes may provide

additional insight into the accuracy of low-flow characteristics estimated using the techniques in this report.

The techniques may be used only for natural, unregulated or partially regulated, and non-tidal streams outside the Mississippi River alluvial plain. The techniques for transferring the 7Q10 from gaged sites to ungaged sites are not considered to be representative for basins outside the range of characteristics used for developing the techniques.

SUMMARY

Mississippi State water laws require that the 7-day, 10-year low-flow characteristic of streams be used as a criterion for issuing waste-discharge permits to dischargers and for limiting withdrawals of water from streams. This report presents techniques for estimating the 7Q10 for ungaged sites on streams in Mississippi based on the availability of base-flow discharge measurements at the ungaged site, location of nearby gaged sites on the same stream, and drainage area of the ungaged site. These techniques may be used to estimate the 7Q10 at sites on natural, unregulated or partially regulated, and non-tidal streams. Low-flow characteristics for streams in the Mississippi River alluvial plain were not estimated because the annual low-flow data exhibit decreasing trends with time.

For ungaged sites with base-flow discharge measurements, the base-flow discharge data are related to concurrent discharge data at a selected gaged site. If more than one base-flow measurement is available, concurrent base-flow discharges at the ungaged site and at the gaged site can be used to determine graphically the 7Q10 for the ungaged site from the 7Q10 at the gaged site. If only one base-flow measurement is available, the discharge-ratio method is used to estimate the 7Q10 for the ungaged site. The discharge-ratio method is based on the assumption that the ratio of concurrent base flows at the ungaged site and at a selected gaged site is equal to the ratio of the 7Q10 for the sites. These techniques are generally more accurate than other methods of estimating the 7Q10 for an ungaged site because they are based directly on streamflow data at the site.

For ungaged sites on gaged streams, several methods of transferring the 7Q10 from a gaged site to an ungaged site were developed. The resulting estimates are based on drainage area prorations between the sites.

For ungaged sites on ungaged streams, the 7Q10 is estimated by multiplying the drainage area at the site by the unit-7Q10 values shown on a map in this report. The mapped values of unit-7Q10 are based on base-flow data for nearby gaged basins and the geology and topography of the ungaged basins. This method is the least accurate of those developed in this study.

- a Could not be determined because of zero values of 7Q10; there is relatively little uncertainty in estimate of 7Q10.
- b Approximately 38 percent of basin has been regulated by Bluff Lake since 1950; figure based on discharge data for regulated and unregulated conditions.
- c Approximately 22 percent of basin has been regulated by Bluff Lake since 1950; figure based on discharge data for regulated and unregulated conditions.
- d Approximately 16 percent of basin has been regulated by Bluff Lake since 1950; figure based on discharge data for regulated and unregulated conditions.
- e Figure based on discharge measurements possibly affected by municipal discharge upstream.
- f Approximately 35 percent of basin has been regulated by Lake Bogue Homo since 1939; figure based on regulated conditions only.
- g Approximately 45 percent of basin has been regulated by Okatibbee Lake since 1968; figure based on regulated conditions only.
- h Site previously published as station number 02479150.
- i Site previously published as station number 02480268.
- j Drainage area not determined because of undefined drainage boundaries.
- k Approximate drainage area.
- l Figure based on discharge measurements possibly affected by industrial and municipal discharge upstream.

Table 2.—Index of streamflow-gaging stations listed alphabetically by station name

[Ref. no. refers to identification number on plate 1 and in table 1]

Station name	Station number	County or Parish	Ref. no.
Abiacha Creek at Cruger, MS	07287160	Holmes	391
Alamuchee Creek near Cuba, AL	02468000	Sumter	59
Albritton Creek near Bogue Chitto, MS	02490350	Lincoln	288
Amite River near Darlington, LA	07377000	St. Helena	492
Archusa Creek near Quitman, MS	02477200	Clarke	121

APPENDIX

Gaging station pairs on the same stream

[Drainage-area ratio is the drainage area at the upstream station divided by the drainage area at the downstream station; discharge ratio is the 7Q10 for the upstream station divided by the 7Q10 for the downstream station; Used in analysis? identifies station pairs used to compute the transfer exponent in equation 2 and relates to data used in figure 5; Exponent for this pair refers to the exponent of the drainage area ratio based on data for this station pair only]

Upstream station number	Downstream station number	Drainage-area ratio	Discharge ratio	Used in analysis?	Exponent for this pair
